**Abstract**— This study aims to evaluate seaweed *Ulva reticulata* preference for available nitrogen forms of eutrophic coastal waters for its growth rate. Simple experiment was developed for laboratorium testing of *U. reticulata* preference for NH₃, NO₂, NO₃ for 20 days. Levels of those nitrogen species and their composition were provided naturally from filtered eutrophic coastal waters of western coast of South Sulawesi Indonesia, without any exchange. The composition of NH₃:NO₂:NO₃ in the eutrophic water of the experiment was 1.0:2.4:3.3. The results showed that the NO₃ was the most preferred form of nitrogen for the growth. The average amount of uptake of NO₂, NH₃, and NO₃ was respectively 4.58 ± 1.71 μg/l/day, 2.70 ± 0.17 μg/l/day, and 1.98 ± 1.19 μg/l/day. The average growth rate of *U. reticulata* was 15.40 ± 3.12 % day⁻¹.

**Keywords**— Nitrogen preference, *Ulva reticulata*, Seaweed, Eutrophic coastal waters.

**I. INTRODUCTION**

Seawater multicellular macroalga, seaweed aquaculture in Indonesia becomes one of main economic revenues from the coastal and marine sectors, contributing 54.46 % or US$ 129.92 million of Indonesia (Central Bureau of Statistics 2018) Coastal water of south Sulawesi, Indonesia is one of the seaweed aquaculture foci, with production reaches 13 million tones per annum. Instead of providing revenue and livelihood for coastal community, the seaweed aquaculture plays a significant role in abating coastal eutrophication resulting from fish aquaculture, as one of the targets of SDG 14. The use of aquaculture seaweed (or even multitrophic model) for coastal eutrophication abatement has increased scientific attention over the last two decades (Troell & Berg, 1997; Bates et al., 2001). It lies on the capacity of seaweed to readily uptake nutrient (Choi et al., 2009; Luo et al., 2012; Martínez and Rico, 2012; Bulboa, 2014; Rabie et al., 2014; Brundu and Chindris, 2018). Seaweed uses nutrients (N and P) as a food source for growth and development. Nitrogen is assimilated into amino acid constituent, while phosphorus is a major source of chemical energy for photosynthesis (Graham & Wilcox, 2000). This capacity to absorb nutrients is then sought to be an alternative mitigation measures of eutrophication in the waters.

The health of ecosystems and their use in coastal areas is an indicator of water quality, especially in the field of marine conservation and various activities in other fisheries sectors. Aquaculture and agricultural effluents are a major challenge in maintaining the quality of waters in coastal areas, where increased concentrations of nutrients i.e. nitrogen, phosphorus and silicon from these activities can cause eutrophication of waters which have a negative impact on organisms. This condition has been found in the waters off the west coast of South Sulawesi where nutrient enrichment is quite large (Lukman et al., 2014; Nasir et al., 2015) and symptoms of eutrophication have been identified (Nurfadillah, 2016). Waste discharges from aquaculture, especially shrimp and fish ponds, and agriculture have been recognized as are the main sources of nutrient enrichment causing cultural eutrophication and impacting the coastal ecosystems in the western coast of South Sulawesi (Nasir et al., 2016; Hopkins et al., 1995). The availability of excessive nutrients cause changes in the composition of community.
structures in marine ecosystems such as microorganisms (Kegler et al., 2017), plankton (Nasir et al., 2015) and coral reef ecosystems (Teichberg et al., 2018; Edinger et al., 1998). Therefore efforts to overcome eutrophication or nutrient pollution need to get serious attention. Increased nutrient in coastal waters can be mitigated by increasing nutrient partition coefficient in the aquatic compartments which absorb or consume these nutrients (Carpenter, 2008). Absorption by seaweed can accumulate and store organic materials such as nitrogen in thallus cells (Boyajian & Carriera 1997). Organic waste stored in seaweed thallus cells will be degraded through photosynthetic assimilated sunlight to produce energy used for growth (Boyajian & Carriera 1997).

Furthermore, from an economic standpoint, the Indonesian government encourages increased seaweed aquaculture and industrialization as a response to increasing demand for seaweed commodities both on a national and international scale (Radiarta et al., 2016). The potential and quality of Indonesian seaweed attract demands from various countries in the world. There are more than 550 types of seaweed in Indonesia and most of the products from seaweed has been exported as dried seaweed as well as processed forms. These various opportunities owned by one of the biological resources in Indonesia make seaweed can be used as a superior export product (Ditjen PEN, 2013).

However, a comprehensive study of the preference of any particular seaweed, for instance Ulva reticulata, to all forms of available nitrogen – ammonia (NH$_3$), nitrite (NO$_2$), and nitrate (NO$_3$) - as nutrients in waters in the context of eutrophication is still relatively lacking and even non-existent, especially in the South Sulawesi region. Therefore, research on the ability to nutrient uptake seaweed is important, to optimize seaweed aquaculture and eutrophication mitigation effort. This is also to developing application of ecosystem-based seaweed farming, a sustainable cultivation system that is a world trend (FAO, 2011).

II. RESEARCH METHOD

This study used Ulva reticulata taken from the Lae-lae Island, and cultivated in the laboratory under their natural condition. As much as 72 grams of the Th increasing rate (or equivalent to nutrient uptake) of NO$_2$, NH$_3$, and NO$_3$ was 4.58 ± 1.71 μg/l/day, 2.70 ± 0.17 μg/l/day, and 1.98 ± 1.19 μg/l/day, respectively. It indicated that the NO$_3$ become Ulva reticulata preference nutrient uptake in the eutrophic coastal waters. Compared to other Ulva reticulata in this experiment took up nutrient less than other experiments (Table 1). It is most likely due to that there was no nutrient additional inputs into the water systems, so the available nutrient in the experimental aquarium gradually lessen was prepared for each aquarium filled with filtered 42-liter eutropic coastal waters taken from the western coast of south Sulawesi, Indonesia, without any exchange for 20-day period of experiment. Moreover, each of the aquarium was light-enriched with 1,561 lux, and small pump was introduced in the aquarium to obtain slow movement of water. The experiment was undertaken in triplicates, with additional control experiment in also triplicates. Concentration measurements of NH$_3$, NO$_2$, and NO$_3$ were carried every 10 days, using APHA method (1989) with trichlorometric spectroscopy. Seaweed weights was measured for growth. Seaweed growth was calculated using the method adopted by Balina et al (2017). Water quality was checked in situ for parameters: temperature, pH, salinity and dissolved oxygen. Absorption nutrients by seaweed were calculated from the rate of decrease in nutrients in the water column. With the formula, the rate of decline = (T1-T2) / t. Where t is the monitoring period, T1 is the initial nutrient concentration and T2 is the final nutrient concentration.

III. RESULT AND DISCUSSION

3.1. Decreased nutrient concentration (N)

The initial concentrations of NH$_3$, NO$_2$, and NO$_3$ were respectively 0.05 mg/l, 0.120 mg/l, and 0.163 mg/l. All the nutrient experienced decreasing in concentration during the experimental period (Fig 1). Significant decreased in nitrogen availability compared to the control experiments indicates nutrient uptake by the Ulva reticulata. Changes in this composition showed that NO$_2$ experienced higher decrease in the concentration than the other NH$_3$ and NO$_3$ species. NO$_3$ decreased 1.8% from the initial concentration. While, NO$_3$ was decreased by around 0.20% and NH$_3$ around 0.13% during the trial period. The decrease in concentration of the three forms of nitrogen (NO$_3$, NO$_2$, and NH$_3$) shows that seaweed is very requires nitrogen in nutrients the period of its growth (Wahyudi, et. al., 2018).
3.2. Nutrient Uptake

The decreasing rate (or equivalent to nutrient uptake) of NO₂, NH₃, and NO₃ was 4.58 ± 0.71 μg/l/day, 2.70 ± 0.17 μg/l/day, and 1.98 ± 1.19 μg/l/day, respectively. It indicated that the NO₂ become Ulva preference nutrient uptake in the eutrophic coastal waters. Compared to other Ulva in this experiment took up nutrient less than other experiments (Table 1). It is most likely due to that there was no nutrient additional inputs into the water systems, so the available nutrient in the experimental aquarium gradually lessen.

3.3. Effect of seaweed growth on nutrients (N)

The growth rate of Ulva reticulata is linear until the end of the trial (20 days). The average growth rate is 15.40 ± 3.12% day⁻¹. Fig. 1 reflects the effect of each species of nitrogen on the rate of growth. The negative impact on growth is only shown by NH₃ with a slope of -1780 (R² = 0.880) . Positive trends in growth are shown by NO₂ and NO₃ with slope of 146.4 (R² = 0.718) and 68.66 (R² =
The highest decrease in NO$_2$ concentration in the absorption process by *Ulva reticulata* was also found in a study conducted by Rabie, 2014. The relationship of NO$_2$ absorption to *Ulva reticulata* seaweed growth was explained by Marinho-soriano, et al., 2011 that the high ability of *Ulva reticulata* to absorb NO$_2$ is a strategy to get a large amount nitrogen which is useful for growth.

3.4. Water Quality Condition

Experimental water quality provided sufficient condition for seaweed cultivation and nutrient preference experiments. The water quality was maintained almost stable during the period of experiment. ANOVA test results for water quality parameters ($p > 0.05$; Table 2). The salinity remained in the average of 30 - 31 $\%_o$. pH varied between 7.8 and 8.10. Water temperature was between 29 – 30 $^\circ$C, and dissolved oxygen (DO) was in the range of 5.63 to 6.38 mg/l.

IV. CONCLUSION
Without exchanging of water meaning no additional nutrient in the experiment, the preference of Ulva reticulata in eutrophic coastal waters of western coast of south Sulawesi, Indonesia was to NO$_2$. The uptake of the NO$_2$ was 4.58 ± 1.71 μg/l/day, and the growth rate of the seaweed was 15.40 ± 3.12 % day$^{-1}$. The experimental condition was stable indicating water quality had no significant impact to the growth.
